The prevalence of obesity is increasing worldwide, and with dietary and lifestyle changes, the number of obese people in Korea is on the rise. According to statistics, 28 percent of the Korean female population is obese, and the proportion of obese pregnant women is also increasing \cite{1}. Obesity is classified based on the body mass index (BMI, kg/m$^2$), and a BMI over 30 is defined as “obesity.” The World Health Organization divides obesity into three classes based on BMI, that is, Class 1: 30.0 to 34.9 kg/m$^2$, Class 2: 35.0 to 39.9 kg/m$^2$, and Class 3: $\geq$ 40 kg/m$^2$ \cite{2}. Some argue that among Asians, including Koreans, different standards of BMI should be applied compared to Westerners’ but the present study does not consider the difference in BMI between races, which is beyond the scope of this study \cite{3}. Obesity is classified as a high-risk factor with changes in the respiratory and cardiovascular systems, especially in pregnant women. It also causes problems in anesthetic management due to an increased risk of cesarean section, technical difficulties associ-
ated with regional anesthesia, and airway problems related to general anesthesia. Obese parturients should try to control their weight during pregnancy so that they do not reach an obese level because obesity increases the risk to both the fetus and the mother. The weight-gain recommendation guidelines (Table 1) are presented according to the BMI level before pregnancy, and weight control through exercise and diet control leads to safe delivery by preventing obesity [4]. The weight gap between delivery and self-reported pre-pregnancy is defined as the gestational weight gain (GWG). Although GWG as an indicator is reportedly more effective, BMI is a more common and universal method for clinical application, and thus, BMI is more commonly used in practice. This review describes safe analgesic techniques for labor and anesthetic management of cesarean sections in obese parturients.

GENERAL CHARACTERISTICS

Definition

BMI is the most common statistical tool used to assess obesity. The weight and height are required for BMI calculations and are typically determined using the weight and height measured in the clinical setting or the self-reported weight and height of individuals. BMI is the weight divided by height (kg/m²). Obesity is defined based on the World Health Organization’s international classification of adult BMI; individuals with a BMI ≥ 30 are obese. This classification of BMI is used in individuals of the white, black, and Hispanic races. There is some debate about the World Health Organization classification because the cut-off values underestimate the risk of obesity in Asian and South Asian populations. In Asian and South Asian populations, some investigators insist that the cut-off value of BMI should be 25 or higher [5].

Prevalence

In Korean women, the frequency of obesity above BMI 25 is reported to be 28.1 percent for women aged 19 and older and 30.4 percent for women aged 30 and older [1]. Although lower than the percentage of obese women reported in Western countries, this increase in the number of obese women has been pointed out as a threat to the health of pregnant women and fetuses. The exact figure for the proportion of obese people among pregnant women in Korea is yet to be determined, however, it is estimated to be increasing.

Physiologic changes

1. Respiratory system

Pregnancy affects the oxygenation and ventilation of parturients, and the physical, mechanical, and hormonal changes associated with pregnancy bring lead to changes to the respiratory tract. In obese parturients, obstructive sleep apnea is not uncommon, but pregnancy itself has some protective effect on sleep apnea despite nasal passage edema and hyperemia. In the early stages of pregnancy, increased sensitivity of the respiratory center reduces apneic events, and in the second half of pregnancy, parturients tend to lie on their sides and sleep, reducing the possibility of airway obstruction. Long-lasting hypoxemia, hypercapnia, and pulmonary hypertension in obese parturients significantly increase maternal morbidity and mortality [6,7]. Despite being a lower abdominal surgery, cesarean sections can lead to reduced lung capacity and volume in obese parturients compared to non-obese parturients [8]. Weight increase in pregnancy further increases the breathing workload, and obese parturients need more energy to move their weight-bearing chest walls during ventilation. The increased abdominal weight limits the movement of the diaphragm, which intensifies in the supine and Trendelenburg positions, reducing the tidal volume. Fortunately, not all changes related to pregnancy in patients with obesity are harmful. The respiratory function can be slightly improved in parturients [9]. In particular, the functional residual capacity is improved. Hormonal changes reduce airway resistance through the relax-

anation effects of progesterone on smooth muscles, reducing some of the negative effects of obesity on the respiratory system [10,11]. While studies have shown that the respiratory effects of obesity are minimal in sitting positions during pregnancy, supine positions can change the volume, flow, and mechanical characteristics of respiration.

2. Cardiovascular system

A wide range of cardiovascular changes can occur as the oxygen demand increases during pregnancy, and the pathological changes caused by obesity have serious effect on cardiac, endothelial, and vascular functions. Pregnancy has a rather favorable effect on the respiratory system, while more serious side effects are seen in the cardiovascular system. Pregnancy can worsen previous obesity-related endocrine, inflammatory, and microvascular changes [12]. The degree of secondary cardiovascular pathological changes in obesity depends on the duration and severity of obesity [13]. Excessive extra fat increases the cardiac output. The increase in cardiac output is 30–50 ml/min for every 100 g of fat accumulated in the body. Therefore, the blood volume of obese parturients increases accordingly. The volume load initially leads to left ventricular hypertrophy, after which the myocardium begins to expand due to the increased pressure overload. The heart rate increases with the increased cardiac output, decreasing the diastolic interval and myocardial perfusion time. Damaged myocardial diastolic relaxation further leads to myocardial relaxation. Fat deposition in myocardial tissues can have a serious effect on conduction and contractility. Therefore, systolic or diastolic dysfunction can occur frequently in the left ventricle. Patients with pulmonary hypertension and obstructive sleep apnea may experience right ventricular impairment. Congestive heart failure is a result of additional stress [14]. The effect of the enlarged uterus compressing major blood vessels in the abdomen and causing supine hypotensive syndrome (SHS) can also be seen in obese parturients. This can worsen significantly in obese parturients, where a large panniculus with an enlarged uterus exacerbates uterine compression. This problem can be extended after surgery if the panniculus is large enough to compress the blood vessels. There have been reported cases of postoperative sudden cardiac arrest in morbidly obese surgical patients that remain unexplained after autopsy. The autopsies showed no pathology to explain the cardiac arrest in such cases [15].

3. Gastrointestinal system

The anatomical and hormonal changes associated with pregnancy increase the incidence and severity of gastric reflux in parturients. Obesity increases the risk of gastric aspiration under general anesthesia, and hiatal hernia may be more common in obese parturients. When pregnancy is associated with obesity, the chances of regurgitation and aspiration increase significantly. Some researchers have reported that the gastric volume of obese parturients is five times greater than that of non-obese parturients in labor [16].

4. Diseases associated with morbid obesity in pregnancy

Diabetes and hypertension are common problems during pregnancy. Continuous inflammation and pregnancy-related hormonal changes in obese patients worsen blood glucose levels. Major complications reported to be related to obesity during pregnancy include hypertension, diabetes mellitus, respiratory disease, thromboembolic disorders, infections, and an increased risk of postpartum hemorrhage. The association between obesity and hypertension, diabetes mellitus, and an increased incidence of cesarean section is well known [17,18]. In addition, labor-related complications such as an increased rate of instrumental delivery, failure to progress, intrapartum fetal distress, meconium aspiration, abnormal fetal presentation, and shoulder dystocia are common in obese parturients [19]. Furthermore, the success rate of vaginal delivery after cesarean surgery has been shown to decrease proportionally with increased maternal BMI [20,21]. The incidence of post-delivery endometriosis and wound infections is considerably higher in obese patients [19]. Obesity itself is a high-risk factor for both increased delivery-related blood loss and postpartum hemorrhage [22]. A meta-analysis showed that the odds ratios of a cesarean section in obese parturients were 1.46 (overweight, 95% confidence interval [CI]: 1.34–1.60), 2.05 (obese, 95% CI: 1.86–2.27), and 2.89 (severely obese, 95% CI: 2.28–3.79), relatively higher than that in normal weight pregnant women [23]. According to the literature, obese parturients have a 14–25% prevalence of preeclampsia, a 6–14% prevalence of gestational diabetes, and a 30–47% incidence of cesarean sections [17]. Parturient obesity is highly associated with an increased risk of fetal macrosomia, fetal death, and birth defects [24–26]. Many studies have reported an increased risk of neural tube defects, omphalocele, fetal heart defects, and multiple anomalies [25]. In addition, obesity itself makes it difficult to detect fetal anomalies in the early stages with diagnostic ultrasound. The high incidence of fetal anomalies in morbidly
obese parurients may be due to the inability to adequately evaluate the fetus because of maternal obesity and underlying maternal medical diseases such as preeclampsia and diabetes mellitus.

**ANESTHETIC MANAGEMENT**

Obese pregnant women have a high incidence of comorbid diseases, and therefore, they need to be thoroughly evaluated and prepared before anesthesia at an early stage. An appropriate-sized blood pressure cuff should be used for noninvasive blood pressure measurements because if the width of the cuff is relatively small compared to the arm circumference, the blood pressure measurement can show higher values. Therefore, the blood pressure cuff is sometimes applied on the mother’s forearm to avoid this problem. The blood pressure with forearm measurements correlate well with the upper arm measurements, but exceed an average of 10 mmHg. Conical noninvasive blood pressure cuffs for obese patients were introduced and used in clinical settings and are known to correlate well with measured arterial blood pressure values [27]. If blood pressure measurements using noninvasive blood pressure methods do not reflect the actual blood pressure, invasive blood pressure measurements using intra-arterial catheters may be more useful. Obesity can cause difficulties in securing intravenous lines; therefore, appropriate veins should be secured early in delivery. If a peripheral venous line cannot be secured, intravenous cannulation under ultrasonic guidance or the central vein should also be considered. Sufficient manpower is essential for the transport of obese patients. In addition, beds, mobile carts, and operating tables that can withstand proper size and weight are also checked in advance. Sufficient pads may be required to place obese patients on labor beds or operating tables, and a long spinal or epidural Tuohy needle may be required.

**Analgesia for labor**

Analgesia for labor is effective and important for a good outcome of the fetus and good satisfaction of the parturient. Neuraxial analgesia is effective and useful for reducing labor pain in parturients. For obese mothers, the epidural analgesic technique is the best and safest way to provide labor analgesia [28]. It is the best way to provide a good pain relief effect during the labor phase, and can be easily converted to surgical anesthetic conditions in the case of cesarean section, if required. Since the incidence of fetal macrosomia is high, epidural analgesia can help in the successful management of shoulder dystocia. Therefore, frequent evaluation for well-functioning epidural catheters is extremely important to verify that the epidural method can be reliably extended to provide appropriate surgical anesthesia, if required. However, the insertion of the epidural catheter in obese parurients is technically more difficult compared to that in non-obese parurients. Anesthesiologists have more difficulties in the identification of the midline in the lumbar spine, detection of epidural space, and placement of epidural catheters in obese parurients. Knee-chest positioning in the lateral decubitus is comparatively more difficult to sustain in the obese parturient than in the non-obese group. Gravity in the lateral decubitus position can also force the panniculus down, which obscures the midline of the lumbar spine. For this reason, the sitting position is preferred to easily locate the midline for epidural catheterization. More objectively, the midline can be identified under ultrasound, and the epidural space can be found using images to measure the depth from the skin to the epidural space. In pregnant women, ultrasound imaging before epidural catheterization can significantly reduce the number of attempts and help identify the correct intervertebral space and epidural depth. However, viewing ultrasound images is more difficult in obese parurients, and the fact that all anesthesiologists are not familiar with using ultrasound is still considered a limitation. The distance from the skin to the epidural space increases in proportion to BMI: 4.4 cm in mothers of normal weight and 7.5 cm in BMI 50 and above [29] (Table 2). Therefore, even in obese parurients, a typical Tuohy needle can be used to identify the epidural space; therefore, it is preferable to use a standard-length epidural Tuohy needle at first, which can be

Anesthesia in morbidly obese parturients

Anesthesia for cesarean section

Anesthesiologists need thorough preparation, especially in obese parturients, prior to cesarean section. In particular, anesthesiologists should evaluate parturient airways completely prior to general anesthesia. Even if neuraxial anesthesia is performed, a thorough evaluation of the airway is needed because the anesthetic technique can be converted to general anesthesia due to inadequate sensory blockade or prolonged operation time. In obese pregnant women, intubation and manipulation of blade handling can be difficult because of the large breasts, increased anterior-posterior chest diameter, airway swelling, and shortening of the jaw and chest spacing. When laboring mothers present to the operating room for cesarean section, many staff members are required to move the parturient from the ward bed to the operating table. In the presence of a neuraxial blockade, it is difficult to safely bring an obese mother to the operating table. This shift poses a potential risk of injury to both the parturient and the staff supporting this transition. It can be very difficult to properly and safely position obese pregnant women in a surgical bed for a cesarean section, which must be supplied with right wedges for left-uterus displacement. In addition, medical staff must securely fasten the obese parturient to the bed to prevent falls before tilting to the left. However, it is more important to position the left uterus as soon as possible because SHS appears relatively faster and can be more serious than that in normal-weight pregnant women. Pulling the panniculus toward the head of a morbidly obese pregnant woman can cause pressure on the upper abdomen and chest, reducing venous return and cardiac output, resulting in hypotension.

Regional anesthesia

Neuraxial blocks are the ideal anesthetic method and gold
can be used as a guide for the spinal needle as a needle through the needle CSE method. In an obese parturient, the operation time can be longer than expected, and therefore, the CSE technique provides the advantage of rapid onset and intense block for prolonged operation with postoperative pain control. In addition, a lower dose of intrathecal bupivacaine can be administered, and the level of block can be adjusted with an epidural catheter to achieve adequate surgical anesthesia. In parturients with severe cardiovascular disease, a lower dose of intrathecal bupivacaine and slowly titrated local anesthetics lead to minimal hemodynamic changes, and therefore, a sudden onset of hypotension may be prevented effectively. CSE has a beneficial effect on obese parturients with cardiovascular diseases.

**General anesthesia**

In Korea, approximately 28.8% of cesarean sections have been performed under general anesthesia over the past five years [35], but the rate of general anesthesia limited to the obese parturient group has not yet been reported. The rate of general anesthesia in Korea is significantly higher than that in Western countries [36]. Considering that the fatal complication rate is high under general anesthesia, if possible, it would be desirable to replace general anesthesia with regional anesthesia. Owing to the anatomic and physiologic changes in obese mothers, difficult intubation and urgent desaturation can occur in such patients. Therefore, proficient assistance may be needed to maintain airways. The jaw-thrust maneuver can also require the use of both hands of the anesthesiologists, and therefore, other staff may be needed for positive pressure ventilation and downward pressing on the cricoid cartilage. Various equipment (such as laryngoscope with short blades, supraglottic airway devices, video laryngoscope, fiberoptic intubation devices, Bullard laryngoscope, or cricothyrotomy devices) should be prepared for difficult intubation situations. If intubation fails, the intubation failure algorithm must be started, and help must be requested immediately [37]. If intubation is expected to be difficult, rapid sequence induction is recommended, and during apnea, pregnant women fall into hypoxia faster, with obese mothers reaching hypoxia even faster; therefore, sufficient preoxygenation should be performed before initiating general anesthesia. Proper parturient positioning for the best laryngoscopic view can assist in securing a difficult airway. The ramped position improves the laryngoscopic view compared to the traditional sniffing position and can be accomplished by elevating the head of an obese parturient above the shoulders by modifying the operating table or by applying blankets under the upper body [38,39] (Fig. 1). As soon as the parturient is transferred to the operating table, the facial mask is firmly fixed to the face, and oxygen administration begins subsequently. Preoxygenation is an essential process for delaying the desaturation of obese mothers and providing sufficient oxygen. The dosage of induction anesthetics in obese women should be calculated based on the ideal body weight rather than the actual weight [40]. Succinylcholine and rocuronium are widely used as neuromuscular blockers for rapid tracheal intubation during general anesthesia. One study attempted to determine the appro-

---

Anesthesia in morbidly obese parturients

Propriate dose of succinylcholine for the ideal intubating condition in the non-pregnant morbidly obese group, concluding that 1.0 mg/kg based on the total body weight provides both complete paralysis and satisfactory intubating conditions [41]. Alternatively, rocuronium may be administered to provide an adequate laryngoscopic condition at a dose of 1–1.2 mg/kg based on ideal body weight [42]. Sugammadex can be administered to reverse the neuromuscular blocking induced by rocuronium or vecuronium in a short time [43]. In the supine position under general anesthesia, early closure of small airways due to decreased functional residual capacity, administration of volatile anesthetics, neuromuscular blockers, and cephalad retraction of the panniculus may lead to pulmonary hypoxemia. Many interventions (high tidal volumes, high inspired oxygen, and the use of positive end-expiratory pressure) have been used to maintain appropriate arterial oxygenation. Tracheal extubation should only be attempted in fully awake parturients with appropriate reversal of neuromuscular blockers, as failed extubation may occur easily in obese parturients [44]. A 30° head-up tilting is an excellent position for tracheal extubation in obese patients compared to a simple supine position [45].

Postoperative management

The risk of postoperative complications (hypoxemia, pulmonary atelectasis, deep vein thrombosis, pulmonary edema, postpartum cardiomyopathy, and wound complications) is very high in the obese parturient group [46]. Moreover, a BMI-dependent decrease in respiratory function may occur even after regional anesthesia [47]. Postoperative pulmonary events may lead to severe complications. Therefore, postoperative early ambulation has also been reported to improve respiratory function during the postoperative period [47]. In morbidly obese parturients, postpartum complications occur after cesarean section and do not occur after vaginal delivery [44]. Postoperative pain should be properly controlled and reduced to facilitate postoperative mobilization and lung care because postoperative pulmonary complications are very important determinants of prognosis. PCEA with dilute local anesthetics mixed with opioids may improve the quality of postoperative pain relief. The risk factor of thrombosis is associated with pregnancy, cesarean section, and obesity, and postoperative pulmonary thromboembolism remains a major cause of maternal mortality. Both pharmacological and mechanical interventions can be used for prophylaxis; therefore, perioperative use of an adequate anticoagulant and intermittent pneumatic compression are recommended [48]. In obese parturients, postoperative wound complications occur more frequently than in the non-obese group, which often leads to prolonged recovery and long hospitalization, and the midline vertical abdominal incision is associated with a higher incidence of wound complications than a Pfannenstiel incision [49]. Morbidly obese parturients may be hospitalized for significantly longer duration because of the increased incidence of postoperative complications and antepartum medical disease. The length of hospital stay and costs in morbidly obese parturients have been shown to increase after both vaginal delivery and cesarean operations [50].

CONCLUSIONS

The high prevalence of obese parturients may lead to maternal and fetal morbidity and can also increase the incidence of side effects from labor, cesarean section, and anesthesia; therefore, careful evaluation and preparation before delivery and surgery is needed in such cases. Prior to the cesarean section for obese parturients, detailed communication between the anesthesiologist and obstetrician regarding the parturients’ medical condition and details of surgery and anesthesia for the parturient should be established. Neuraxial anesthetic techniques are the gold standard method in morbid parturients, but neuraxial anesthesia may be converted to general anesthesia because of the prolonged operation time or technical failure; therefore, airway evaluation and equipment for airway assistance must be in place at all times. For rapid recovery from surgery, adequate postoperative pain control and an adjusted anticoagulant dose for an appropriate duration are recommended. Careful observation of airway obstruction is required in morbid parturients because respiratory depression after delivery and obstructive sleep apnea can occur in such cases.
